#### ABSTRACT

Numerical tables available for  $M/E_k/c$  queueing systems are discussed. A new approximation method for steady-state information and waiting time distribution of this queueing system was developed. Validity of approximation was established directly for the large waiting times and by simulation for the smaller values. The developed method enables one to find delay probability, expected number in the queue and in the system, expected time to be spent in the queue and in the system, and probability of waiting for more than a specified time  $t$ .

#### ACKNOWLEDGEMENT

The author wishes to acknowledge the help and guidance of Professor R. R. Read of Naval Postgraduate School, Monterey, California. The author is also indebted to his wife Saba, whose understanding during the preparation and typing the draft of this thesis meant a lot to him.

## I. INTRODUCTION AND SUMMARY

Multi-server queues constitute a large proportion of queueing systems which arise in practice. Among those, queues with Poisson arrivals and Erlang service times (which will be denoted as  $M/E_k/c$ ) occupy an important position, as seen in the banks, airport check-in counters, hotels, supermarkets etc. However, no significant theoretical work was done until the late 60's. In recent years, methods for the steady state solution of  $M/E_k/c$  queues became available, followed by the numerical tables which were obtained by implementation of these methods. Even so, there is still some computational difficulty involved obtaining some particular information about above-mentioned queues, such as probability of delay exceeding a specified time length.

The importance of the  $M/E_k/c$  queue is due to the fact that it is used to model any queueing system whose service time distribution is believed to be unimodal. The solutions are known for extreme values of  $k$ : exponential service time distribution for  $k=1$  and constant service times as  $k \rightarrow \infty$ . Usable solutions for multi-server queues having either exponential or constant service times are readily available. The  $M/E_k/c$  queue is also important by providing a large variety of service time distributions in between these two extremes.

The purpose of this study is, by means of computer simulation and examination of numerical tables published earlier, to present a simple and accurate computation method for obtaining information about steady-state solution of the  $M/E_k/c$  queue.

For this purpose, a general description of  $M/E_k/c$  queuing model with definitions and assumptions for the analysis of it are given in Chapter II, followed by a summary of former studies.

In Chapter III, the numerical tables are analyzed and some conclusions are drawn in terms of a simple form approximation for steady-state distribution of waiting times.

This approximation for the distribution of waiting times needed verification for small values of them. These cases were studied by computer simulation. The procedure and the results of simulation are given in Chapter IV.

The results of the analysis of numerical tables and simulation are combined and generalized in Chapter V. Then the computational method developed by this generalization is described on a step-by-step basis. With this method, there is no need for numerical tables, computations are very simple, and the results are accurate for most practical purposes (the error being about 2% in general). To demonstrate the advantages of the proposed method, a comparison of it with the other method which uses numerical tables is given at the end of that chapter.

## II. The M/E<sub>k</sub>/c Queue

The description of the M/E<sub>k</sub>/c queueing model with assumptions, definition of parameters and system variables along with some basic definitions in the queueing theory forms the first half of this chapter. A brief discussion of the previous studies on this model then follows.

### A. DESCRIPTION OF THE SYSTEM

The M/E<sub>k</sub>/c queue is a multi-server queueing system with  $c$  servers, where arrivals occur according to a Poisson process with rate  $\lambda$ , and service times have Erlang distribution with shape parameter  $k$ . It is also an infinite queue, i.e. there is no limitation for the number of customers in the system.

The distribution of interarrival times  $X$  is given by

$$f_X(x) = \lambda e^{-\lambda x}, \quad x \geq 0$$

and the service times have the following probability density function:

$$f_Y(y) = \frac{1}{(k-1)! \beta^k} \cdot y^{k-1} e^{-y/\beta}, \quad y \geq 0$$

with mean  $k\beta$  and variance  $k\beta^2$ .

## 1. Definitions of Parameters

### a. Arrival Rate and Service Rate

Arrival rate to the system is the reciprocal of mean interarrival time and denoted by  $\lambda$ . Similarly, service rate of a server is defined as reciprocal of mean service time and represented by  $\mu$ . Then,  $\mu = \frac{1}{k\beta}$ .

### b. Traffic Intensity

Traffic intensity  $\rho$  is defined by the following expression:

$$\rho = \lambda/c\mu .$$

### c. Offered Load

Offered load is the ratio of arrival rate  $\lambda$  to service rate  $\mu$  and denoted by  $\alpha$ . It can also be expressed by product of number of servers  $c$  and traffic intensity  $\rho$  as follows

$$\alpha = c\rho .$$

### d. Coefficient of Variation

The ratio of standard deviation to mean is defined as coefficient of variation of a probability distribution. It is denoted by  $V$ . For Erlang distribution coefficient of variation is expressed as

$$V = \frac{\sqrt{k\beta^2}}{k\beta} = \frac{1}{\sqrt{k}} .$$

## 2. System Variables

### a. Number in the System

The total of the number of customers waiting in the queue and those in the service is defined as number in the system and denoted by  $N$ . The number of customers only in the queue is represented by  $N_q$ . Expected values of  $N$  and  $N_q$  are denoted by  $L$  (average number in the system) and  $L_q$  (average number in the queue), respectively.

### b. Waiting Time

The time spent in the queue by a customer is defined to be the waiting time of a customer. The time spent in the system is then the sum of waiting time and service time of a customer.  $T_q$  denotes waiting time and  $T$  denotes the time spent in the system. Expected values of  $T$  and  $T_q$  are denoted by  $W$  (average time in the system) and  $W_q$  (average waiting time) respectively.

### c. State Probabilities

The number in the system at a particular time is defined as the state of the system. Then state probability  $P(N = n|t)$  is the probability of the system being in state  $n$  at time  $t$ .

### d. Delay Probability

Delay probability is the probability that the arriving customer finds all the servers busy and enters the waiting line. It is denoted by  $P(T_q > 0)$ . Also, by definition it follows that

$$P(T_q > 0) = P(N \geq c).$$

### 3. The Steady-State Solution

The steady-state solution is defined to be the probability distribution of the number in the system when the system achieves statistical equilibrium. In the steady-state, the state probabilities do not depend on  $t$ , i.e.  $P(N = n|t) = P(N = n)$ . Also it follows that

$$\sum_{n=0}^{\infty} P(N = n) = 1 .$$

In queueing theory, it is a well-known fact that [1] the steady-state is achieved if and only if the traffic intensity  $\rho$  is less than 1.

### 4. Assumptions

The  $M/E_k/c$  queueing system under study is assumed to have the following properties:

- (i) There is only one waiting line no matter how many servers there are.
- (ii) The customer at the head of the waiting line starts getting service immediately whenever a server becomes available.
- (iii) Order of service is first-come first-served.
- (iv) If an arriving customer finds all servers busy, he joins the waiting line. The waiting line has unlimited capacity.
- (v) The service channels (servers) are indexed consecutively. If an arriving customer finds more than one

server vacant, he goes to the server with smallest index (this assumption doesn't cause any loss of generality, but is convenient for the computer simulation model).

(vi) The servers are homogeneous, i.e. the service distribution is the same for all servers.

(vii) Only one customer at a time can be served by a server.

#### B. FORMER STUDIES

There are numerous studies in the literature of queueing theory, done for the steady-state solution of  $M/E_k/c$  queue. But most of them cover only some particular values of  $k$  and  $c$ , and their results cannot be generalized. Therefore, such studies will not be mentioned here individually.

The earliest suggestion known by the author about the solution of general  $M/E_k/c$  system was mentioned by Lee [2]. He stated referring to a case study done in 1956 that mean waiting time can be approximated by use of David Owen's suggestion. The formula given in [2] was said to be usable for  $0.7 \leq V \leq 1.0$  and as follows,

$$W_q = \frac{1}{2} W_{q1} (1+V^2)$$

where  $W_q$  : mean waiting time for  $M/E_k/c$  queue

$W_{q1}$  : mean waiting time for  $M/M/c$  queue

$V$  : coefficient of variation of Erlang ( $k$ ) distribution,  $V^2 = 1/k$ .

The validity of the approximation was demonstrated by comparing its results with simulation results for different

cases. However, the approximation is just for mean waiting time or queue length, hence it isn't possible to approximate state probabilities. Also, no reference was given for details of David Owen's suggestion. This approximation will be mentioned again later in this study.

The steady-state solution of the general  $M/E_k/c$  queue was first studied by Mayhugh and McCormick [3]. The results can be applied to the cases with any value of  $k$  and  $c$ . However, the computation procedure is so complex that it requires a very considerable amount of work.

A parallel study was also done by Heffer [4]. The solution method proposed by Heffer differs from Mayhugh and McCormick's, but it also is very complex.

The reader is referred to the references [5] and [6] for more detailed discussion of these two studies.

The most recent study was done by Yu [5]. It concerned the  $E_m/E_k/c$  queue with heterogeneous servers, but results were also stated for homogeneous server case. Then letting  $m = 1$  gives the solution procedure for  $M/E_k/c$  queue. However, like the other two studies, the computations required still demand an enormous amount of work.

The theoretical results obtained by Heffer [4] and Yu [5] formed the basis of the only numerical tables available for  $M/E_k/c$  queue, prepared by Hillier and Lo [6]. The tables have cases of  $M/E_k/c$  queue with limited values of  $k$  and  $c$  ( $k \leq 8$ ,  $c \leq 10$ ), and a few cases for  $E_m/E_k/c$  queue. These tables will be discussed in detail in the following chapter.

### III. DISCUSSION OF NUMERICAL TABLES AND DEVELOPING A NEW COMPUTATION METHOD

In this chapter, a detailed review and discussion of the numerical tables given in [6] will be made. Then, using the results of these discussions, a new computation method will be developed.

Sample pages from the numerical tables are given in Appendix B.

#### A. DISCUSSION OF NUMERICAL TABLES

##### 1. General Description

The tables under consideration were designed for general  $E_m/E_k/c$  systems. The analysis however will be focused on the cases in which  $m = 1$  (i.e.  $M/E_k/c$  system), which forms a large proportion of the tables. As mentioned earlier, the values of  $k$  and  $c$  for various tables are as follows:

$$k=2; c=1,2,\dots, 10$$

$$k=3; c=1,2,\dots, 5$$

$$k=4; c=2,3$$

$$k=5,6,\dots,8; c=2$$

The information given in each table is:

- (i) State probabilities,  $P(N=n)$ , and
- (ii) Cumulative state probabilities,  $P(N \leq n)$ , for  $n=1,2,\dots;$
- (iii) Delay probability,  $P(T_q > 0)$ ;
- (iv) Expected number in the system,  $L$ ;

- (v) Average queue length,  $L_q$ ;
- (vi) Average queue length for the equivalent M/M/c system with the same arrival and service rates,  $L_{q1}$ .
- (vii) The ratio  $L_q/L_{q1}$ .

All this information is given in each case and for the following values of traffic intensity  $\rho$  :

$$\rho = 0.10, 0.20, \dots, 0.50, 0.55, \dots, 0.95, 0.98, 0.99.$$

So, all the information is given for steady-state conditions.

Average queue length  $L_{q1}$  for the equivalent M/M/c system is computed by using the following formula [7],

$$L_{q1} = \frac{(c\rho)^c}{c!(1-\rho)^2} p_0 \quad (3.1)$$

where

$$\frac{1}{p_0} = \sum_{j=0}^{c-1} \frac{(c\rho)^j}{j!} + \frac{(c\rho)^c}{c!(1-\rho)}$$

The rest of the information given in the tables was computed by the results of theoretical work mentioned in the last chapter, done by Heffer and Yu.

## 2. Use of Tables

The kind of information listed above can be obtained directly from the tables. However, by making use of some general relationships in the queueing theory, some other information can be obtained besides those mentioned above.

### a. Interpolation

No interpolation method is specified in the explanation sections for the tables in [6], for the values of

$\rho$  different from those given above. The default position taken is linear interpolation.

b. Waiting Times

The average waiting time  $W_q$  and average time in the system  $W$  are frequently of interest in the analysis of queueing systems. These values can be obtained from the tabulated values of  $L_q$  and  $L$  respectively, by using the following relationships [8],

$$W_q = \frac{L_q}{\lambda}, \quad W = \frac{L}{\lambda}.$$

The probability  $P(T_q > t)$  that waiting time exceeding  $t$  is also important in the analysis of queueing systems. Although this kind of information is not given in the tables,  $P(T_q > t)$  can be approximated from the state probabilities,  $P(N=n)$ , as follows:

$$P(T_q > t) = \sum_{n=c}^{\infty} P(N=n) P\{D \leq [k(n-c+1)-1]\}, \quad t \geq 0,$$

(3.2)

where  $D$  is a Poisson random variable with mean  $ck\mu t$ . The reader is referred to the discussion in [6] for the stochastic reasoning of this relationship. The quantity  $P\{D \leq [k(n-c+1)-1]\}$  can be obtained from Poisson distribution tables with mean  $ck\mu t$ . If this mean exceeds 25, then the

normal distribution with the same mean and variance can be used as an approximation to Poisson distribution.

### 3. Discussion

#### a. Delay Probabilities

Similar to  $M/E_k/c$ ,  $M/M/c$  denotes a multi-server queueing system with Poisson arrivals of rate  $\lambda$  and exponential service times of service rate  $\mu$ . The delay probabilities for  $M/M/c$  queue can be computed by using the formula [7],

$$P(T_q > 0) = \frac{(c\rho)^c}{c!(1-\rho)} \frac{1}{\left( \sum_{j=0}^{c-1} \frac{(c\rho)^j}{j!} + \frac{(c\rho)^c}{c!(1-\rho)} \right)} \quad (3.3)$$

A chart is also available in Appendix A for  $c=2, 3, \dots, 15$  and  $0 < \rho < 1$ , for  $P(T_q > 0)$ .

A comparison of delay probabilities of  $M/E_k/c$  and  $M/M/c$  systems for selected values of  $\rho$ ,  $c$  and  $k$  is given in Table I of this study. A careful examination of this table shows that the corresponding delay probabilities of the two systems for the same value of  $\rho$  are very close. Since the formula or charts are available for  $M/M/c$  system, this comparison shows that they can also be used to estimate delay probabilities for  $M/E_k/c$  system with a very small error, usually less than 0.01.

b. Average Queue Length and Number in the System

A careful examination of the "Ratio" column of Table I in [6] indicates that

$$\lim_{\rho \rightarrow 1} \frac{L_q}{L_{q1}} = \frac{k+1}{2k} = \frac{1}{2}(1 + \frac{1}{k}) = \frac{1}{2}(1 + v^2) \quad (3.4)$$

which is essentially the same as Owen's suggestion [2]. However, it works beyond the limits of coefficient of variation  $v$  that were stated by Owen. Also (3.4) is true even when  $\rho$  is markedly less than one. The theoretical verification for (3.4) was developed by Yu in [9].

A more precise approximation formula was also developed by Hillier and Lo in [6] which provides more accuracy for small values of  $\rho$ . In this case, the approximation formula is given by

$$L_q \approx \frac{1}{2}(1+g) \left(1 + \frac{1}{k}\right) L_{q1} \quad (3.5)$$

where  $g = f(\rho, k, c)$ . Then the expression for  $g$  has been obtained by linear regression. The exact coefficients for  $g(\rho, k, c)$  are given in [6]. However, a rougher expression which is more convenient for computations will be used here, given as

$$g = \frac{1}{12} \left( \frac{k-1}{k+1} \right) (c-1)^{2/3} \left\{ (1-\rho) + (1-\rho)^2 \right\} \quad (3.6)$$

The main purpose of Hillier and Lo for introducing  $g$  into approximation formula (3.5) was to provide means of approximation for the cases with larger  $k$  and  $c$  values which were not covered in [6], namely, extrapolation for larger values of  $c$  and  $k$ . One way to check the validity of the computational formula for  $g$  is to first let  $k$  go to infinity, then compare the values of average waiting time  $W_q$  computed by the formula given below with average waiting time  $W_{qD}$  of M/D/c queue. This latter queue has Poisson arrivals with rate  $\lambda$  and constant service times of length  $1/\mu$  (or  $k\beta$ ), and one can use the fact that the distribution of service times can be approximated by constant service time distribution for very large  $k$  as mentioned in Chapter I.

The computation formula for  $W_{qD}$  of M/D/c queue is given in [2] as follows,

$$W_{qD} = \sum_{i=1}^{\infty} e^{-ia} \left[ \sum_{j=ic}^{\infty} \frac{(ia)^j}{j!} - \frac{1}{\rho} \sum_{j=ic+1}^{\infty} \frac{(ia)^j}{j!} \right]$$

However, a more convenient form for computations can be obtained as

$$W_{qD} = \sum_{i=1}^{\infty} \left[ \frac{e^{-ia} (ia)^{ic}}{(ic)!} + \left(1 - \frac{1}{\rho}\right) \sum_{j=ic+1}^{\infty} \frac{e^{-ia} (ia)^j}{j!} \right]$$

(3.7)

which permits the use of Poisson distribution tables. But it still requires a great deal of computational work. Fortunately, a very convenient chart was developed by Shelton [10] for  $W_{qD}$  for  $1 \leq c \leq 100$  and  $0.10 \leq \rho \leq 0.96$ .

The comparison mentioned above can be made having the necessary tools available and Table II can be used for this purpose. The values of  $W_{qD}$  for  $M/D/c$  system were obtained from Shelton's charts. Average waiting time  $W_q$  for  $M/E_k c$  system is computed by using the following formula,

$$W_q = \frac{1}{2\lambda} \left[ 1 + \frac{1}{12} \left( \frac{k-1}{k+1} \right) (c-1)^{2/3} \{ (1-\rho) + (1-\rho)^2 \} \right] (1 + \frac{1}{k}) L_{q1}$$

where  $L_{q1}$  is computed from (3.1). If the expression given by (3.6) is true for very large values of  $k$ , then it should also be true that

$$\lim_{k \rightarrow \infty} W_q = W_{qD}$$

Taking the limit of  $W_q$  gives

$$\lim_{k \rightarrow \infty} W_q = \frac{1}{2\lambda} \left[ 1 + \frac{1}{12} (c-1)^{2/3} \{ (1-\rho) + (1-\rho)^2 \} \right] L_{q1}$$

On the other hand, if  $g$  is omitted, the limit will then be

$$\lim_{k \rightarrow \infty} W_q = \frac{1}{2\lambda} L_{q1} = \frac{1}{2} W_{q1}$$

A comparison of  $W_{qD}$  and these two limits for eight different cases is given in Table II. Investigation

TABLE II.

Comparison of $W_{qD}$ and Limits of $W_q$ With or Without $g$					
Case No	c	$\rho$	$\frac{1}{2} W_{ql}$	$W_q (k=\infty)$	$W_{qD}$
1	2	0.80	1.185	1.209	1.08
2	2	0.80	1.422	1.451	1.296
3	5	0.90	2.287	2.34	2.16
4	5	0.90	1.144	1.17	1.08
5	10	0.90	1.337	1.391	1.36
6	10	0.90	1.505	1.563	1.53
7	20	0.90	3.305	3.766	3.36
8	20	0.90	5.508	5.88	5.6

of these results shows that, for almost all the cases the limit with  $g$  omitted is closer to  $W_{qD}$  than the other limit. This indicates that the formula (3.6) should be reviewed for large  $k$  values. However, this revision can be done only after some additional tables become available for the cases not covered in [6].

#### c. Waiting Times

The method of approximating the probability  $P(T_q > t)$  that the waiting time will exceed  $t$  using the state probabilities  $P(N=n)$  was described earlier in the chapter. However, this method assumes that an arriving customer will

have to wait for approximately  $k(n-c+1)$  service phase (exponentially distributed with mean  $\beta$ ) completions before a server becomes available to start his service. It is stated in [6] that this approximation for  $P(T_q > t)$  should be better for larger values of  $\rho$  and  $t$  due to this assumption. It should be added that, for large  $k$  and small  $t$ , the approximation fails greatly in representing the actual distribution of waiting times for the same reason.

#### B. NEW COMPUTATION METHOD

The construction of a practical computation method using the facts obtained from the preceding discussions will form the rest of the chapter. This new method is desired to be applicable to the queueing problems involving  $M/E_k/c$  systems met in practice, with simple and quick computational work without any need for tables, interpolations etc.

The kinds of information which are desired to be able to compute by the new method for  $M/E_k/c$  queueing system are mainly

- (i) Delay probability,
- (ii) Average waiting time, average time in the system, average queue length and average number in the system,
- (iii) Probability distribution of delay times and probability that waiting time will exceed a specified time length.

##### 1. Delay Probability

In the discussion earlier it was pointed out that the delay probabilities  $P(T_q > 0)$  for the systems  $M/E_k/c$  and

M/M/c are very close for the same value of  $\rho$ . An examination of the comparisons given in Table I shows that the delay probabilities are very close for M/M/c ( $k=1$ ), M/E<sub>k</sub>/c ( $k>1$ ) and M/D/c ( $k=\infty$ ) systems with the same value of  $\rho$ .

The differences between the delay probabilities for the same  $\rho$  are less than 0.01 for almost all the cases and gets even smaller for  $\rho$  close to one. This comparison suggests that delay probabilities of the M/M/c system can be used for corresponding M/E<sub>k</sub>/c system also. These delay probabilities are computed by using formula (3.3). The formula is not suitable for large values of  $c$ , however, and a chart is given in Appendix A for up to about 16. For greater values of  $c$ , the charts are also available in [10] and [11].

## 2. Average Queue Length and Average Waiting Time

In the previous discussion, after examination of the tables in [6] it was concluded that the average queue length for M/E<sub>k</sub>/c system can be approximated by

$$L_q = \frac{1}{2}(1+g) \left(1 + \frac{1}{k}\right) L_{q1} \quad (3.8)$$

where  $L_{q1}$  is computed according to (3.1), and  $g$  is computed by

$$g = \frac{2}{12} \frac{k-1}{k+1} (c-1)^{2/3} \left\{ (1-\rho) + (1-\rho)^2 \right\}.$$

Contribution of  $g$  in equation (3.8) is negligible for practical purposes in most cases. Also it was shown earlier in this chapter that the formula  $g$  requires some

modifications. Therefore it will be omitted in further discussions.

Now, attention will be focused on equations (3.1) and (3.3). Rewriting equation (3.1) in a different form, then substituting (3.3) gives

$$L_{q1} = \frac{\rho}{(1-\rho)} \cdot \frac{(c\rho)^c}{c!(1-\rho) \left[ \sum_{j=0}^{c-1} \frac{(c\rho)^j}{j!} + \frac{(c\rho)^c}{c!(1-\rho)} \right]} \quad \text{and}$$

$$L_{q1} = \frac{\rho \cdot P(T_q > 0)}{(1-\rho)}$$

Then it follows that

$$W_{q1} = \frac{L_{q1}}{\lambda} = \frac{P(T_q > 0)}{c\mu(1-\rho)}$$

Using (3.8) with  $g=0$ , some approximation formulas for average queue length and average waiting time are obtained respectively as follows

$$L_q = \frac{1}{2} \rho \frac{P(T_q > 0)}{(1-\rho)} (1 + \frac{1}{k}) \quad (3.9)$$

$$W_q = \frac{1}{2} \frac{P(T_q > 0)}{c\mu(1-\rho)} (1 + \frac{1}{k}) \quad (3.10)$$

where  $P(T_q > 0)$  is delay probability for M/M/c system which can be obtained from the charts very easily. Then it is very simple to compute  $L_q$  and  $W_q$  using equations (3.9) and (3.10).

The average number in the system  $L$  and average time in the system  $W$  can be computed by following well-known relationships of queueing theory,

$$L = L_q + \frac{\lambda}{\mu} , \quad W = \frac{L}{\lambda} .$$

### 3. Waiting Time Distribution

Suppose that the conditional waiting time distribution given  $T_q > 0$  for  $M/E_k/c$  queueing system can be approximated by

$$P(T_q > t | T_q > 0) = e^{-bt} .$$

Then using Bayes' theorem it follows that

$$P(T_q > t) = P(T_q > t | T_q > 0)P(T_q > 0) = e^{-bt} P(T_q > 0) . \quad (3.11)$$

Let  $F_{Tq}$  be the CDF of waiting times. Then

$$F_{Tq}(t) = 1 - P(T_q > 0) e^{-bt} , \quad t \geq 0 .$$

Now average waiting time can be computed as follows

$$W_q = E(T_q) = \int_0^\infty (1 - F_{Tq}(t)) dt = \int_0^\infty P(T_q > t) e^{-bt} dt$$

$$W_q = \frac{P(T_q > 0)}{b} . \quad (3.12)$$

Suppose the parameter  $b$  is modeled as

$$b = \frac{2c\mu(1-\rho)}{(1+v^2)}$$

Then,

$$w_q = \frac{P(T_q > 0)}{2c\mu(1-\rho)} (1+V^2) \quad (3.13)$$

where  $V$  is coefficient of variation of service time distribution. Notice that equation (3.13) is exactly the same as equation (3.10). However, there can exist some other waiting time distribution to give the same average waiting time as given by (3.13), so it must be shown that for  $M/E_k/c$  system, the distribution of waiting times can be approximated by

$$F_{Tq}(t) = 1 - P(T_q > t) e^{-\frac{2c\mu(1-\rho)t}{(1+V^2)}}, \quad t \geq 0 \quad (3.14)$$

If (3.14) is true, then  $P(T_q > t)$  computed by (3.11) should be approximately equal to the one obtained by the procedure suggested by Hillier and Lo [6] which uses state probabilities as described earlier by equation (3.2). Table III gives the comparison of  $P(T_q > t)$  values obtained by these two different formulas for various values of  $t$ . It should be recalled that approximation by state probabilities is poor for small values of  $t$ . However, for  $t > w_q$  the two results agree very well. The difference is ease of computations. Equation (3.11) is much easier than equation (3.2) to compute the same value.

The validity of approximation (3.14) for small values of  $t$  will be shown by simulation, which forms the next chapter. Then the suggested computation method will formally be described on a step-by-step basis in last chapter.

TABLE III.  
Comparison of the Two Approximation Methods

System Parameters				$P(T_q > t)$		Probability that waiting time exceeds $t$					
$c$	$k$	$p$	$w_q$	Case	$t=0.1$	$t=0.5$	$t=1.0$	$t=2.0$	$t=3.0$	$t=4.0$	$t=5.0$

I. Computed by the procedure with state probabilities, eq. (3.2)  
 II. Computed by using exponential approximation, eq. (3.11)

#### IV. COMPUTER SIMULATION

A computer simulation model for  $M/E_k/c$  system is used to investigate the validity of approximation for waiting time distribution introduced in the preceding chapter. Validity of this approximation for moderate and large values of  $t$  was demonstrated in the same chapter. Therefore, analysis will now be focused on the approximation for small values of  $t$ .

##### A. COMPUTER PROGRAM

###### 1. Model

Since the model used to construct the simulation program is based on the same assumptions as stated in Chapter II, it won't be described again in this chapter. The computer language selected was SIMSCRIPT which is especially convenient for simulation of multi-server queueing systems. The reader is referred to [12] and [13] for a brief idea about SIMSCRIPT if he is not familiar with this language. Main reference for SIMSCRIPT however is [14].

One way to check for small  $t$  the validity of approximation distribution developed earlier is to keep the frequency table of waiting times of the customers during the simulation. Let  $M(t)$  be the number of customers with waiting time greater than  $t$  and  $M$  be total number of customers

served during simulation period. Then the estimator for probability of waiting time greater than  $t$  is

$$\widehat{P(T_q > t)} = \frac{M(t)}{M} \quad (4.1)$$

This value can be compared with the value given by the approximation formula to check its validity.

The computer program is given in Appendix B. It is written in the way that it would be possible to obtain the estimates of all kinds of information about the queueing system being simulated; average waiting time and average queue length, state probabilities, delay probability etc. However, only the estimates given by (4.1) will be discussed here.

## 2. Variance Reduction

One of the problems encountered in the simulation of queueing systems is the high variability of waiting times, especially when traffic intensity  $\rho$  is high. Also strong positive correlation between the waiting times of consecutive customers causes serious errors if the standard formula is used to estimate the sample variance of waiting times since this formula will underestimate the true variance [1].

There are several methods developed to overcome this difficulty with high variability. Interested reader can find comprehensive information in references [12], [15] and [16]. The variance reduction method which will be used here is antithetic variates.

In the simulation program, two different random number streams are used to generate interarrival and service times. Once a uniform variate between 0 and 1 is generated, then the random variate from a desired distribution can be obtained by

$$x = F_x^{-1}(u) \quad (4.2)$$

where  $u$  is a uniform variate between 0 and 1 and  $F_x^{-1}$  denotes the inverse of CDF of  $X$  [12]. Then, for example, a sequence of exponentially distributed random variates with mean  $1/\lambda$  can be obtained from a stream of uniform variates by using

$$x = \frac{-1}{\lambda} \ln(u) \quad (4.3)$$

Let  $z_1$  and  $z_2$  be estimators of a parameter, obtained from two different simulation samples and  $z_3 = \frac{1}{2} (z_1 + z_2)$ . Then

$$\text{Var}(z_3) = \frac{1}{4} \text{Var}(z_1 + z_2) = \frac{1}{4} [\text{Var}(z_1) + \text{Var}(z_2) + \text{Cov}(z_1, z_2)] \quad (4.4)$$

which implies that maximum negative correlation between  $z_1$  and  $z_2$  would minimize  $\text{Var}(z_3)$ . This can be obtained by using  $1-u$  in (4.2) in place of  $u$  for random variate generation in the second simulation run.

During the simulation, a random sequence of large service times or short interarrival times would cause long

waiting times and conversely. Using the procedure described above, a sequence of large waiting times would become sequence of short waiting times in the second run; in other words, the waiting times in two different runs will be negatively correlated. Let  $P_i(t)$  be the probability that waiting times will exceed  $t$  in the  $i$ th run,  $i = 1, 2$ . Using antithetic variates,  $P_1(t)$  and  $P_2(t)$  will be negatively correlated; then the estimator will be computed by

$$\hat{P}(T_q > t) = \frac{1}{2}(P_1(t) + P_2(t))$$

where  $P_1(t)$  and  $P_2(t)$  are computed according to (4.1).

Generation of antithetic exponential variates for interarrival times is given by (4.3). However, it is not straightforward to generate antithetic Erlang variates since the CDF cannot be inverted in closed form. Generating Erlang variates as sum of  $k$  exponential variates with mean  $\beta$  does not help since equation (4.2) cannot be utilized to obtain antithetic variates. Nevertheless, one way to solve this problem is to store the CDF table of chi-square distribution in an array, then compute  $F_x^{-1}(u)$  by linear interpolation to get a chi-square random variate, and obtain the Erlang variate by the following transformation

$$E_k = \frac{1}{2} \beta C_k$$

where  $E_k$  is the Erlang variate with mean  $k\beta$  and  $C_k$  is the chi-square variate with degrees of freedom  $k$ . The tables for CDF of chi-square distribution are available in [17].

### 3. Data Collection

#### a. Selection of Input Parameters

The input values for each pair of runs were arbitrarily selected to give certain traffic intensity  $\rho$  values, usually 0.8 and 0.9 in order to get a wider range of waiting times even though they cause high variability. The width of frequency intervals was chosen to be 0.25 min. so that  $f_1$ , for example, would show the number of customers with waiting time less than 0.25 minutes. Then  $M(t)$ , the number of customers with waiting time greater than  $t$  can be computed by

$$M(t) = \sum_{i=4t+1}^{\infty} f_i$$

since  $t$  will be in multiples of 0.25. This computation is done in the computer program.

#### b. Initial and Final Conditions of the System

Initial and final conditions of the simulated system are important since they effect the value of parameter estimated. The approach taken in this study was to use epochs. If the time at which the number in the system  $N$  changes from 0 to 1 by an arrival is defined as a regeneration point, then the interval between two successive regeneration points can be defined as an epoch [12]. It is obvious that the sequences of waiting times in two different epochs will be independent from each other. The epochs tend to be lengthy with high traffic intensity  $\rho$ , large arrival

rate  $\lambda$ , with large number of servers  $c$ , or a combination of these three factors. Before each simulation run, the number of epochs for which the simulation is to be run was determined as an input considering those three factors. Experience showed that the first few epochs tend to have waiting times smaller than usual, so they were omitted for data analysis. This isn't feasible for cases with long epochs; however the first couple of epochs have enough information. The simulation runs were started with  $N = 0$  and an arrival so that starting time would be a regeneration point and stopped after the number of epochs determined earlier is completed, i.e.  $N = 0$  was the final condition.

$P_1(t)$  or  $P_2(t)$  are given in the output of program for  $t = 0.25, 0.50, 0.75, \dots$  etc. Then to get the estimators  $P(T_q > t)$ , all one has to do is to average them for corresponding  $t$  values.

## B. RESULTS

A comparison of waiting time probabilities obtained from simulation and approximation method is given in Table IV. Investigation of this table indicates that the approximation method agrees quite well with the results of simulation for small  $t$  values. The difference between the corresponding values for moderate or large values of  $t$  for which the validity of approximation was demonstrated earlier explains the difference between the values when  $t$  is small.

TABLE IV.  
Comparison of Simulation and Approximation Results

S: Simulation

A: Approximation

## V. CONCLUSION

It was shown in the last chapter that the approximation method developed earlier for the distribution of waiting times can also be used for small values of  $t$ . The method for computing steady-state information of  $M/E_k/c$  queueing system can now be formally described.

### A. DESCRIPTION OF THE PROPOSED COMPUTATION METHOD

After analysis of data and the decision has been made that the particular system under study can be approximated by  $M/E_k/c$  system as described in Chapter II, and also having the estimators for  $\lambda$ ,  $k$  and  $\beta$  obtained (by maximum likelihood or method of moments), one is ready for computations to get the desired information for the system.

#### 1. Delay Probability

First compute service rate  $\mu$  as

$$\mu = \frac{1}{k\beta} .$$

Then compute traffic intensity  $\rho$  and offered load  $\alpha$  by

$$\rho = \frac{\lambda}{c\mu} \quad \text{and} \quad \alpha = \frac{\lambda}{\mu}$$

respectively. Then enter the chart in Appendix A with  $\alpha$  to get delay probability  $P(T_q > 0)$ . Use the charts in [10] or [11] if number of servers  $c > 16$ .

2. Average Waiting Time and Average Queue Length

First compute a system constant, namely  $b$ , by

$$b = \frac{2c\mu(1-\rho)}{1 + \frac{1}{k}}$$

Then average waiting time  $W_q$  is computed as follows

$$W_q = \frac{P(T_q > 0)}{b}$$

Also, average queue length  $L_q$  is given by

$$L_q = \lambda W_q .$$

3. Average Time in System and Average Number in System

Average time in system  $W$  and average number in system  $L$  will be computed by

$$W = W_q + \frac{1}{\mu} \quad \text{and} \quad L = L_q + \frac{\lambda}{\mu}$$

respectively.

4. Waiting Time Distribution

The CDF of waiting times is given by

$$F_{Tq}(t) = 1 - P(T_q > 0) e^{-bt} , \quad t \geq 0$$

where  $b$  is the system constant computed in step 2.

Then the following probabilities can be computed

- (i)  $P(T_q > t_1) = P(T_q > 0) e^{-bt_1}$
- (ii)  $P(t_1 < T_q < t_2) = P(T_q > 0) (e^{-bt_1} - e^{-bt_2})$
- (iii)  $P(T_q < t_1) = 1 - P(T_q > 0) e^{-bt_1}$

as needed by the user.

## B. DISCUSSION

### 1. Advantages of the Method

(i) Needless to say, the most important advantage of the method is simplicity. The kind of information listed above can be computed in minutes given  $c$ ,  $\lambda$ ,  $k$  and  $\mu$  which would be needed to compute anyway. All of the computations can be laid down on one regular size page so that it is very easy to follow by somebody else.

(ii) In most cases, one has to compute the above listed information to determine the effect of changing the number of servers  $c$  on the selected system variables. This multiplies the savings of time and computational effort.

(iii) No tables are necessary except for the delay probability chart. No interpolation would be needed.

### 2. Disadvantages of the Method

(i) Since the method gives an approximation, it is not too precise even though the results are almost always in  $\mp 5$  percent of the actual value, and in  $\mp 2$  percent for most cases.

(ii) The approximation of state probabilities with this method does not appear to be direct.

### 3. Applications

One of the characteristic applications of the queueing theory is to investigate the effect of changing the parameters or number of servers on the measure of effectiveness (MOE) assigned by the management. This measure of effectiveness can be delay probability, average waiting time

or probability of waiting time exceeding time  $t$  etc. The marginal utility of  $c + 1$ st server will be the difference between the values of MOE's for  $c$  and  $c+1$  servers. Then the decision criterion whether or not to hire the  $c+1$ st server is how his cost compares to his marginal utility.

Another managerial objective may be to require, for example, the probability of waiting time exceeds 4 min.,  $P(T_q > 4) = 0.05$ . The number of servers necessary to achieve this purpose will then be of interest.

It is possible to extend the variety of examples. The common property of the above examples is that precision greater than that of suggested approximation is not needed to make the decision.

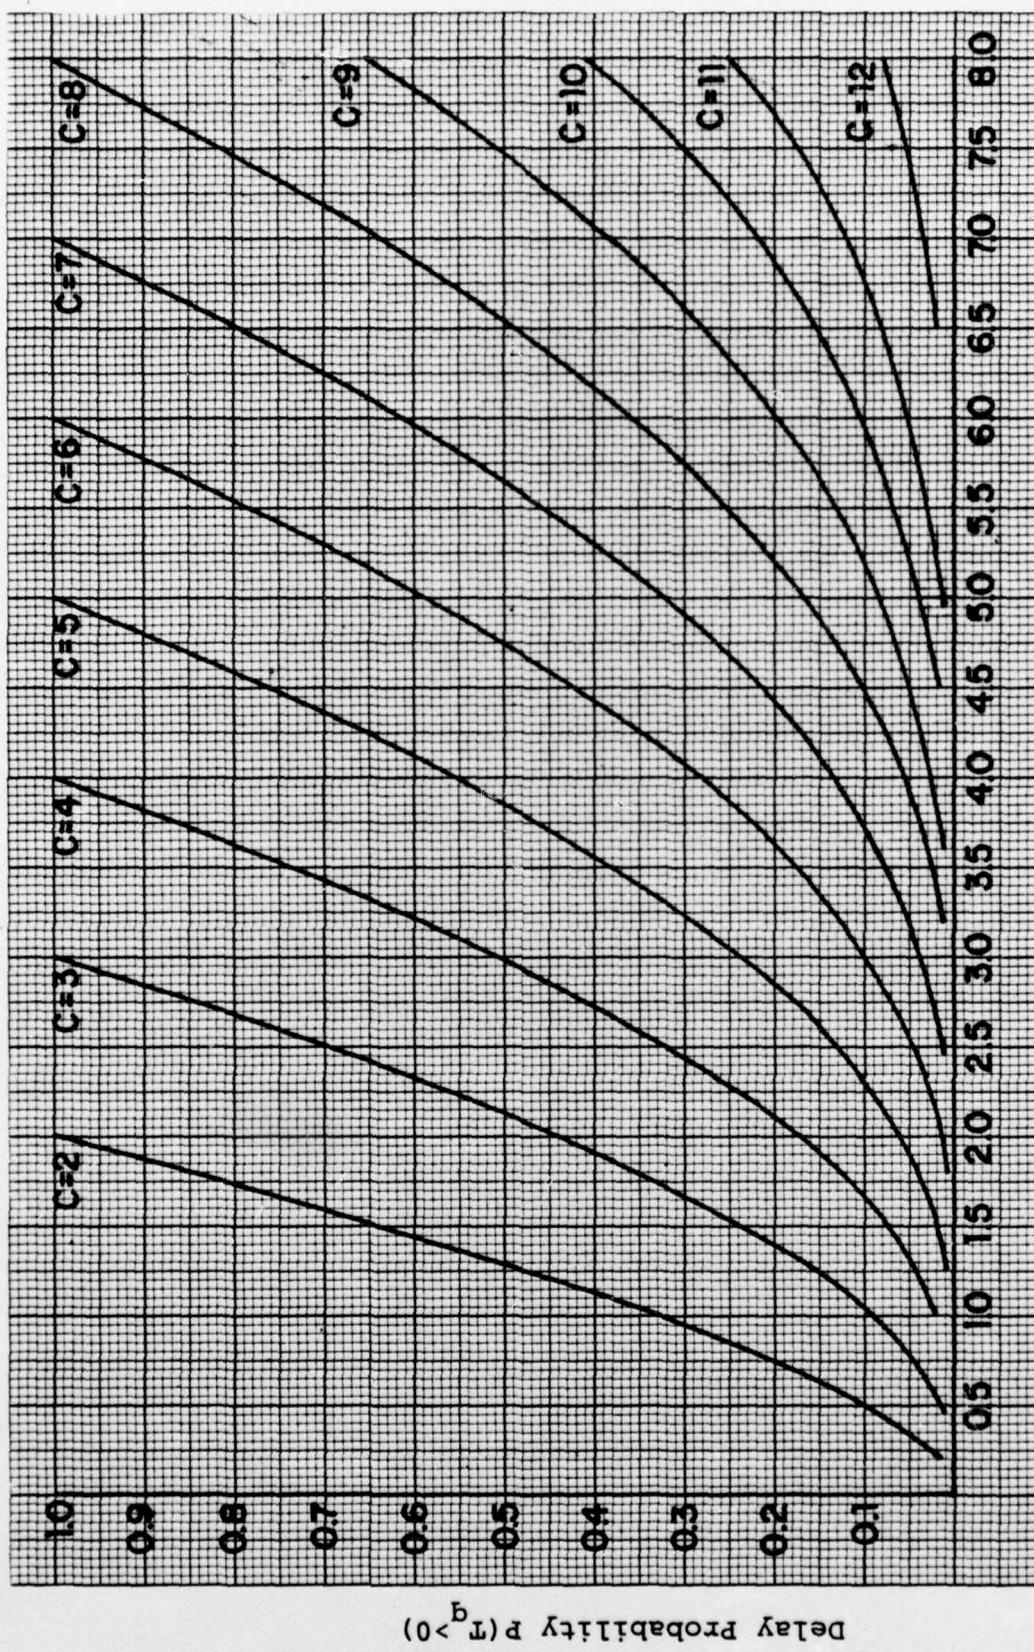

#### 4. Final Remarks

The author wishes to emphasize that without the numerical tables provided by Hillier and Lo [6], it would have been impossible to develop such an approximation method. The method may need some modifications as new tables for the cases not covered in [6] become available.

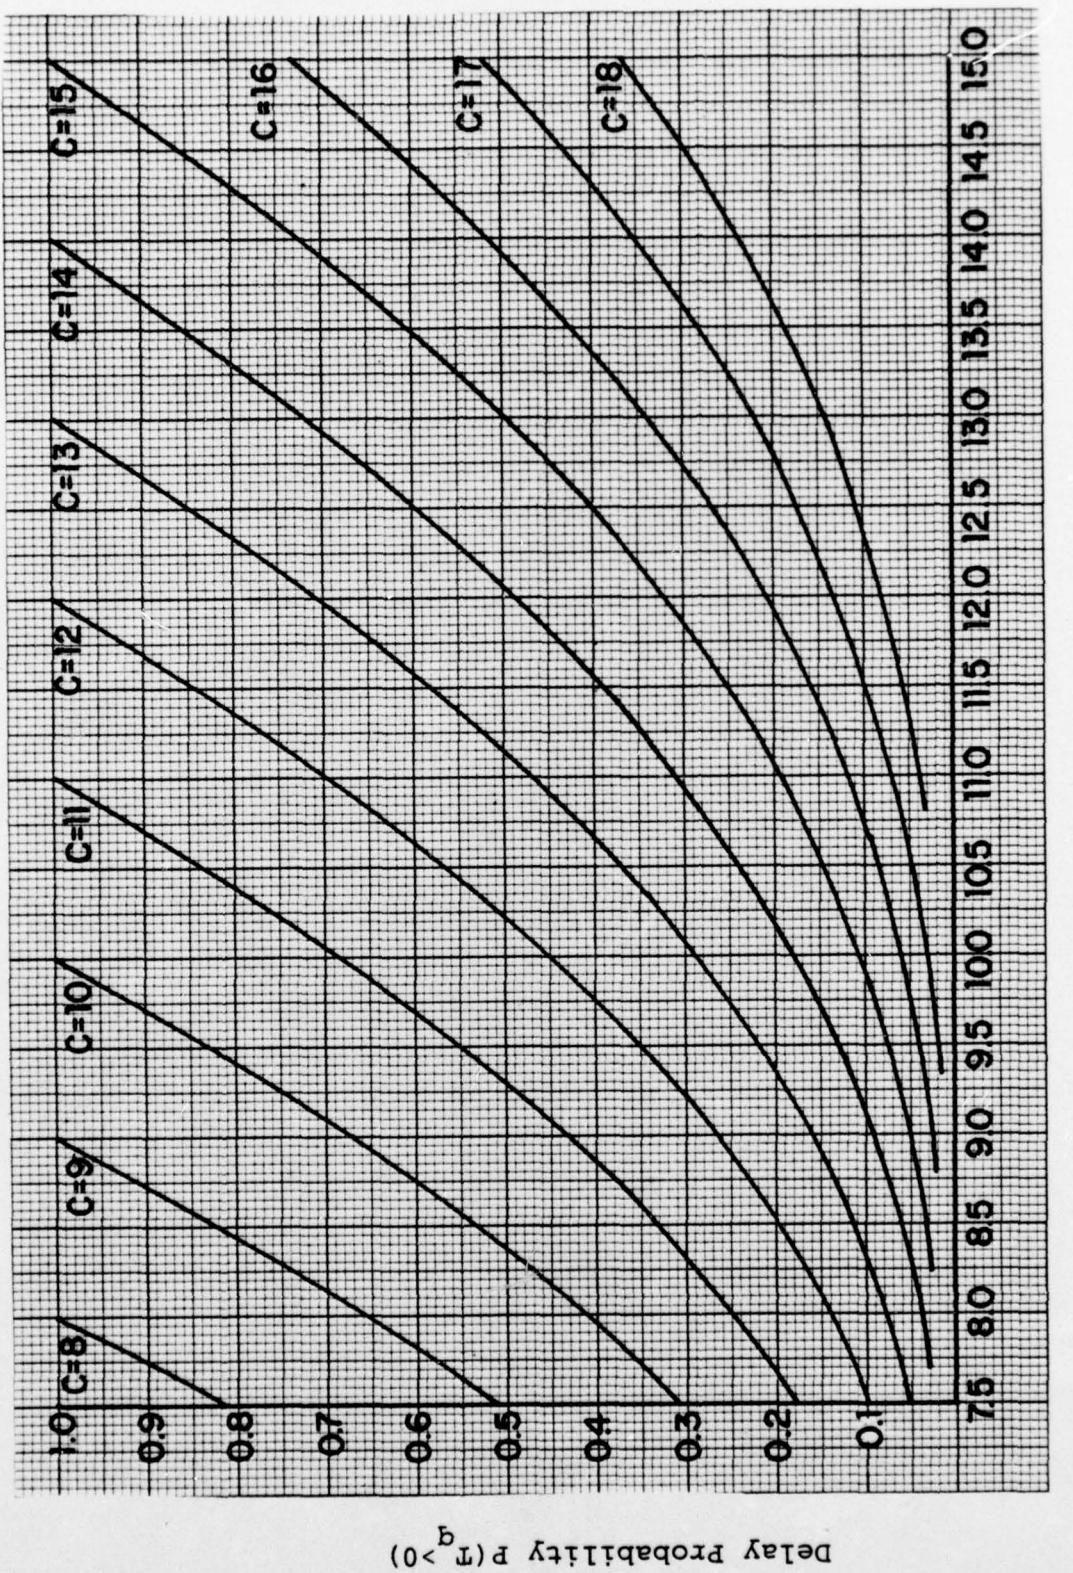

## APPENDIX A

### CHARTS FOR DELAY PROBABILITY

In the two following charts, the delay probabilities can be found for M/M/c system which were shown to be very close to those of M/E<sub>k</sub>/c system, with number of servers c up to about 16. One has to enter to chart with offered load  $\alpha$  as abscissa, then delay probability  $P(T_q > 0)$  is the ordinate value of the point on the proper c curve which has  $\alpha$  as abscissa value.

Delay Probability  $P(T^g > 0)$
